Abstract

Circular electron-positron collider (CEPC) is a dedicated project proposed by China to research the Higgs boson. The collider ring provides $e^+ e^-$ collision at two interaction points (IP). The luminosity for the Higgs mode at the beam energy of 120GeV is 3×10^{34} cm⁻²s⁻¹ at each IP while the synchrotron radiation (SR) power per beam is 30MW. Furthermore, CEPC is compatible with W and Z experiments, for which the beam energies are 80 GeV and 45.5 GeV respectively. The luminosity at the Z mode is higher than 1.7×10^{35} cm⁻²s⁻¹ per IP. Top-up operation is available during the data taking of high energy physics. The status of CEPC will be introduced in detail in this paper.

MACHINE LAYOUT

CEPC [1] which aims at researching Higgs boson is a double ring scheme optimized at the beam energy of 120 GeV. Super proton-proton collider (SPPC) will be the next project after the operation of CEPC in the future. The circumference of CEPC is 100km while matching the geometry of SPPC as much as possible. The circumference is determined by the requirements of SPPC so that the SPPC bending magnets can be designed and manufactured. The arc regions of the SPPC collider ring, the CEPC collider ring and the CEPC booster ring are in the same tunnel. The cross section of the tunnel in the arc region is shown in Fig. 1.

Figure 1: The cross section of the tunnel in the arc region.

† yuch@ihep.ac.cn MOYAA05

The interaction region of SPPC is located in the same long straight sections where the CEPC RF cavities are placed. The collimation region of SPPC with length of about 4km is located in the interaction region of CEPC. Due to the special collision orbit at the IP and the very large size of detector, bypass geometry or independent tunnel for SPPC and CEPC in the two regions is needed. The layout design of CEPC in the RF region and interaction region follows the space constraints. However, it still will be potential space conflict in the two regions during the geometry optimization of SPPC in the future. Since the operation of CEPC will be much earlier than SPPC. So SPPC and CEPC are arranged in the outside and inside respectively. SPPC team can optimize SPPC geometry with relatively lower magnetic field of bending magnet especially in the bypass region. The design of CEPC can keep fixed during the modification of SPPC. The booster ring of CEPC shown in Fig. 1 is located above collider ring with the distance of 2.4 m. The distance is sufficient to avoid the magnetic interference between the collider ring and the booster ring.

Figure 3: The layout of CEPC collider ring.

The layout of CEPC including Linac, transfer lines, booster ring and collider ring is shown in Fig. 2. The Linac is located at ground level with length of 1200 m. The Booster is underground at a depth of approximately 100 m. The Linac and Booster are connected by two transfer lines for e^+ and e^- respectively. These lines have a slope of 1:10. There are 8 straight sections in the collider ring. They are 2 interaction regions, 2 RF regions and 4 injection regions. Among them, two off-axis injection regions are the function regions for the operation of Higgs, W and Z. The two on-axis injection regions are used only during operation in the Higgs mode.

Figure 3 shows the layout of CEPC collider ring. The design of collider ring is optimized at Higgs mode with 650 MHz two cell RF cavities. There are two dedicated surveys in the RF region for the Higgs, W and Z modes. During the operation of Higgs mode all the RF cavities are shared by both e+ and e- beams using combining magnets [2][3] near the RF cavities. Each beam is filled in half ring so that all e+ and e- bunches can pass the RF cavities in turn. This filling scheme in Higgs mode with half the ring won't reduce the luminosity because the required bunch number is relatively small and the bunch spacing is quite large. For the W and Z modes the surveys of e+ and e- rings in the RF region are designed independently by turning off the combined magnets so that all bunches can be filled along the whole e+ and e- rings. The beam current during the operation of W and Z modes is made as much as possible to improve the luminosity. W and Z modes use the same RF cavities which are used in Higgs mode to save cost. Half number of the cavities are distributed in e+ and e- rings respectively for the W and Z modes. The machine parameters for the Z mode do not increase the budget which is based on operation as a Higgs factory.

The central part of the interaction region is shown in Fig. 4. There is a Be pipe of length 14 cm and inner diameter 28 mm. The final focusing magnet is 2.2 m away from the IP. The horizontal crossing angle at the IP is 33 mrad to allow enough space for the superconducting quadrupole coils in a two-in-one type with space for a room temperature vacuum chamber. The accelerator components inside the detector are distributed within a conical space with an opening angle of 13.6°. The luminosity calorimeter is located 0.95~1.11 m away from the IP and has inner radius 28.5mm and outer radius 100 mm.

Twin-aperture dipoles and quadrupoles [4] are in the arc region. The distance between the two beams is 0.35 m. The magnets in the other regions and all the sextupoles are independently powered for flexibility of the optics.

MAIN PARAMETERS OF COLLIDER

The beam stay clear region is defined as \pm (18 σ_x + 3 mm) and $\pm (22 \sigma_v + 3 \text{ mm})$ in the horizontal and vertical directions respectively. Coupling is 1%. The synchrotron radiation (SR) power per beam is limited to 30 MW. The high-energy physics goals of CEPC are to provide e⁺e⁻collisions at a beam energy of 120 GeV and attain a luminosity of 3×10^{34} cm⁻²s⁻¹ at each IP for operation in the Higgs mode. Furthermore, the CEPC should be able to run at 80 GeV and 45.5 GeV for experiments running in the W and Z modes respectively. The luminosity in Z mode is $1.7 \times$ 10^{35} cm⁻²s⁻¹ per IP, and in W mode 1×10^{35} cm⁻²s⁻¹ per IP.

Main parameters of CEPC collider ring is shown in Table 1. The detector solenoid is 3 T with a length of 7.6 m as the baseline design. There are 22 anti-solenoid sections with different inner diameters within the final doublet region at each side of the IP to compensate for the effects on the beam of the strong detector solenoid [5]. For the Higgs mode, with the constraint of 30 MW, the design luminosity per IP is 3×10^{34} cm⁻²s⁻¹ with 242 bunches and beam current of 17.4 mA. The horizontal and vertical β functions at the IP are 0.36 m and 1.5 mm respectively. Operation is in top-up mode. The energy acceptance in Higgs mode is 1.35%. The beam lifetime with the beam-beam effect is greater than 26 minutes.

The Collider lattice in W mode is the same as in the Higgs mode. The design luminosity per IP is 1×10^{35} cm⁻ 2 s⁻¹ with 1524 bunches and beam current of 87.9 mA, again $\overset{\sim}{=}$ with the constraint of 30 MW beam power.

For the Z mode, the horizontal and vertical β functions at the IP are 0.2 m and 1.5 mm respectively to avoid the strong coherent beam-beam instability [6] with the detector solenoid at 3T. The design luminosity per IP is 1.7×10^{35} cm⁻²s⁻¹ with 12000 bunches and beam current of 461 mA. During operation in the Z mode the synchrotron radiation power of each beam can only reach 16.5 MW due to the limitation of HOM heating in the RF cavities and the electron cloud instability in the positron ring. The coupling in þ Z mode is 2.2% which is much larger than expected because the strong fringe field of solenoids leads to a serious coupling growth of both beams. If the detector solenoid work 1 could be 2 T, the coupling can be controlled and the verti-Content from this cal β function at the IP can be reduced from 1.5 mm to 1.0mm so that the luminosity in Z mode per IP can reach $3.2 \times 10^{35} \,\mathrm{cm}^{-2} \mathrm{s}^{-1}$.

THE DESIGN OF INJECTION

The beam stay clear region for the Booster is defined as \pm (4 σ + 5 mm) in both horizontal and vertical directions with a round beam and emittance of 120 nm. This provides sufficient beam lifetime and transfer efficiency during injection and energy ramping. The diameter of the inner aperture of the vacuum chamber is chosen to be 55 mm from considerations of impedance.

The Booster uses 1.3 GHz 9-cell superconducting RF cavities. At the injection energy of 10 GeV from the Linac, the threshold of the single bunch current is $25.7 \,\mu\text{A}$ and the 62th ICFA ABDW on High Luminosity Circular e⁺e⁻ Colliders ISBN: 978-3-95450-216-5

eeFACT2018, Hong Kong, China JACoW Publishing doi:10.18429/JACoW-eeFACT2018-M0YAA05

Figure 5: On-axis injection scheme only for Higgs operation.

threshold of beam current limited by RF power is 1.0 mA. The on-axis injection scheme is shown in Fig. 5. The Linac bunches are injected into the Booster by horizontal on-axis injection at an energy of 10 GeV. At the extraction energies when operating in W and Z modes the circulating bunches of the Booster will be injected into the Collider by horizontal off-axis injection. However, in order to keep a sufficient margin in dynamic aperture, especially with machine errors included, at the extraction energy during Higgs mode operation a special on-axis injection scheme is used, which can significantly relax the requirements on dynamic aperture compared with conventional off-axis injection schemes. First, several circulating bunches from the Collider are extracted to the Booster while the energy is 120 GeV and the beam current limited to 1 mA. The Booster circulating bunches are then merged with the injected bunches from the Collider after 4 damping times. Then, the merged bunches in the Booster are injected back into the Collider by vertical on-axis injection. This procedure will be repeated several times so that all the circulating bunches in the Booster can be accumulated into the Collider. The simulation result indicates that the collision of the stored bunches and the injected bunches is stable. The beam loading effect in the Booster RF system with the same bunch density as the Collider during the on-axis injection procedure in Higgs mode is weak. The maximum cavity voltage drop is 0.48% and the maximum phase shift is 0.63 degree. The peak HOM power per RF cavity is 62 W which is acceptable for the Booster RF system. The dynamic aperture in the Booster is sufficient for vertical off-axis injection from the Collider. The injection duration of both beams during top-up operation are 35.4 s, 45.8 s and 275.2 s for Higgs, W mode and Z mode respectively. The injection intervals with current decay of 3% are 47 s, 153 s and 504 s for Higgs, W mode and Z mode based on beam lifetime. The injection duration from an empty ring are 0.17 h, 0.25 h and 2.2 h for Higgs, W mode and Z mode respectively.

The requirements for sufficient injection efficiency are electron and positron bunch charge of 1.5 nC and repetition rate of 100 Hz. The total beam transfer efficiency from transfer line to the injection point of the Collider is greater than 90% with beam emittance of 120 nm and energy spread of 0.2% at the exit of the Linac. The transfer efficiency can be made much higher with a damping ring of energy 1.1 GeV while the beam emittance of Linac can be reduced to 40 nm. The Linac beam energy is 10 GeV so that magnetic field of Booster dipoles could be 30 Gauss at the injection energy. This is the minimum at which a good quality magnetic field can be obtained.

CONCLUSION

The status of CEPC is introduced in detail in this paper. The design of accelerator physics can meet the luminosity requirements at Higgs, W and Z. The finalization of the beam parameters and the specifications of special magnets have been finished. The hardware devices are all reasonable. The optimization to reduce machine cost and improve the beam performance is always under studying.
